Title: The neighbourhood social environment and alcohol use among urban and rural Scottish adolescents

Kernel density estimation (KDE)

Kernel density estimation (KDE) for spatial point location data produces a smooth, continuous geographic surface for which every location in the study area is assigned a value which can then be used as an independent or dependent variable in statistical models (Carlos et al. 2010). The density of points is calculated using a pre-specified cell size, a kernel function, and a bandwidth (a circle with a radius centred on the focal location) such that the surface is highest above the case (outlet location) and zero at the specified bandwidth from the outlet. The centre of this cell size receives the density value (Chang, 2006). It is important to note that increasing the bandwidth produces a greater smoothing effect (the surface becomes more generalised by reducing the number and magnitude of local maxima) from the original data distribution. The selection of a bandwidth distance that is too large or too small, may over or under-smooth the data (Carlos et al. 2010, Chainey 2013). Therefore, sensitivity analysis is important. Alcohol outlet density has been previously examined using KDE (for example see Carlos et al. 2010).
